# Computing roots of polynomials by quadratic clipping 

Michael Bartoñ ${ }^{\dagger, 1}$ and Bert Jüttler ${ }^{\ddagger, 1}$<br>† Johann Radon Institute for Computational and Applied Mathematics, Austria<br>$\ddagger$ Johannes Kepler University Linz, Institute of Applied Geometry, Austria

#### Abstract

We present an algorithm which is able to compute all roots of a given univariate polynomial within a given interval. In each step, we use degree reduction to generate a strip bounded by two quadratic polynomials which encloses the graph of the polynomial within the interval of interest. The new interval(s) containing the root(s) is (are) obtained by intersecting this strip with the abscissa axis. In the case of single roots, the sequence of the lengths of the intervals converging towards the root has the convergence rate 3 . For double roots, the convergence rate is still superlinear $\left(\frac{3}{2}\right)$. We show that the new technique compares favorably with the classical technique of Bézier clipping.

Key words: root finding, polynomial, Bézier clipping

## 1 Introduction

Efficient and robust algorithms which compute the solutions (systems of) polynomial equations are frequently needed for modeling, processing and visualizing free-form geometry described by piecewise rational parametric representations. For instance, the problem of intersecting a straight line with a rational parametric surface leads to a polynomial system consisting of two equations for two unknowns. If the surface is given in implicit form, then only a single equation has to be solved. Such intersections have to be computed for visualizing free-form surfaces using ray-tracing (Nishita, Sederberg and Kakimoto, 1990; Efremov, Havran and Seidel, 2005). Similarly, the problem of computing the closest point(s) on a curve or surface to a given point leads to polynomial equations (see, e.g., Wang, Kearney and Atkinson, 2003).

[^0]Various geometric problems, such as surface-surface intersections, bisectors / medial axes, convex hull computations, etc., lead to piecewise algebraic curves (Lee, 1999; Patrikalakis and Maekawa, 2002b; Kim, Elber and Seong, 2005). In this situation, efficient methods for analyzing and representing these curves are needed (Gonzalez-Vega and Necula, 2002; Gatellier et al., 2003). Root finding algorithms for (systems of) polynomial equations are again an important ingredient of these techniques; they are used to determine "critical points" (which are needed to determine the topology of the curve) and suitable initial points for tracing the curve.

More precisely, in these and similar applications, all solutions of a (system of) polynomial equation(s) within a certain domain $\Omega$, which is typically a box in $\mathbb{R}^{n}$, are sought for. We are interested in numerical techniques which are guaranteed to find all solutions. Two major approaches exist:

Homotopy methods (see, e.g. Li, 2003; Sommese and Wampler, 2005) start with the solutions of a simpler system with the same structure of the set of solutions. This system is then continuously transformed into the original system, and the solutions are found by tracing the solutions. These techniques are particularly well suited for $\Omega=\mathbb{C}^{n}$.

Bézier clipping and related techniques are based on the convex-hull property of Bernstein-Bézier- (BB-) representations. The main idea is described in Section 2.3. Combined with subdivision, these techniques lead to fast (achieving quadratic convergence for single roots) solvers for univariate polynomials (Nishita, Sederberg and Kakimoto, 1990; Nishita and Sederberg, 1990). Multivariate versions, such as the IPP algorithm, exist and have found their way into industrial software, such as commercial CAD systems (Sheerbrooke and Patrikalakis, 1993; Elber and Kim, 2001; Ko, Sakkalis and Patrikalakis, 2005; Mourrain and Pavone, 2005).

We will formulate a novel technique for computing the roots of univariate polynomials, which is based on degree reduction. This term denotes the process of approximating a polynomial of a certain degree by a lower degree one, with respect to a suitable norm, and possibly subject to boundary conditions. It has been studied thoroughly in the rich literature on this subject (Eck, 1992; Lutterkort, Peters and Reif, 1999; Ahn, Lee, Park and Yoo, 2004; Sunwoo, 2005). In earlier years, the issue of degree reduction was motivated by degree limitations of CAD systems.

The remainder of this paper is organized as follows. In the first section, we give information about the root finding problem, about degree reduction and about the classical technique of Bézier clipping. Section 2 describes the new algorithm and analyzes its order of convergence. In Section 3, we provide a detailed comparison of the new algorithm with Bézier clipping with respect
to criteria such as computational effort, rate of convergence and computing times. Finally we conclude this paper and discuss future work, including the generalization to the multivariate case.

## 2 Preliminaries

After formulating the root-finding problem, we present a simple technique for degree reduction. Finally we describe the classical technique of Bézier clipping for isolating roots of univariate polynomials.

### 2.1 The root-finding problem

Let $\Pi^{n}$ be the linear space of polynomials of degree $n$, with the basis $\left(B_{i}^{n}\right)_{i=0, \ldots, n}$, where

$$
\begin{equation*}
B_{i}^{n}(t)=\binom{n}{i} \frac{(t-\alpha)^{i}(\beta-t)^{n-i}}{(\beta-\alpha)^{n}} \tag{1}
\end{equation*}
$$

are the Bernstein polynomials with respect to a certain interval $[\alpha, \beta] \subset \mathbb{R}$. Any polynomial $p \in \Pi^{n}$ can be described by its Bernstein-Bézier representation with respect to that interval,

$$
\begin{equation*}
p(t)=\sum_{i=0}^{n} b_{i} B_{i}^{n}(t), \quad t \in[\alpha, \beta], \tag{2}
\end{equation*}
$$

with certain Bernstein-Bézier (BB) coefficients $b_{i} \in \mathbb{R}$.
We consider a given polynomial $p \in \Pi^{n}$ in Bernstein-Bézier representation with respect to the unit interval $[0,1]$. All roots of $p$ within the unit interval are to be found. More precisely, we want to generate a set of intervals of maximum length $\varepsilon$ which contain the roots, where the parameter $\varepsilon$ specifies the desired accuracy.

### 2.2 Degree reduction and dual basis

The process of approximating a polynomial $p$ of degree $n$ by a polynomial of degree $k$, where $k<n$, with respect to a suitable norm, is called degree reduction. We consider the spaces $\Pi^{n}$ and $\Pi^{k} \subset \Pi^{n}$, along with the $L^{2}$ inner product

$$
\begin{equation*}
\langle f, g\rangle^{[\alpha, \beta]}=\int_{\alpha}^{\beta} f(t) g(t) \mathrm{d} t \tag{3}
\end{equation*}
$$

with respect to the interval $[\alpha, \beta]$ and the norm

$$
\begin{equation*}
\|f\|_{2}^{[\alpha, \beta]}=\frac{1}{h} \sqrt{\langle f, f\rangle^{[\alpha, \beta]}}, \tag{4}
\end{equation*}
$$

where $h=\beta-\alpha$, induced by it.
In this definition of the norm, the factor $1 / h$ is introduced in order to obtain a norm which is invariant under affine transformations of the $t$-axis. More precisely, for any affine transformation

$$
\begin{equation*}
\mathcal{A}: t \mapsto A_{0}+A_{1} t \tag{5}
\end{equation*}
$$

with $A_{1} \neq 0$, the norms of $f$ with respect to the interval $[\alpha, \beta]$ and of $f \circ \mathcal{A}^{-1}$ with respect to the interval $\mathcal{A}([\alpha, \beta])$ are identical,

$$
\begin{equation*}
\|f\|_{2}^{[\alpha, \beta]}=\left\|f \circ \mathcal{A}^{-1}\right\|_{2}^{\mathcal{A}([\alpha, \beta])} . \tag{6}
\end{equation*}
$$

Applying degree reduction with respect to this norm to the given polynomial $p$ gives the unique polynomial $q \in \Pi^{k}$ which minimizes $\|p-q\|_{2}^{[\alpha, \beta]}$, i.e.,

$$
\begin{equation*}
q=\underset{q \in \Pi^{k}}{\arg \min }\|p-q\|_{2}^{[\alpha, \beta]} . \tag{7}
\end{equation*}
$$

Various techniques for computing $q$ are available (see introduction for references). We describe a simple technique which is based on the dual basis of the Bernstein polynomials.

The dual basis to the Bernstein basis of $\Pi^{k}$ consists of the unique polynomials $D_{j}^{k}$ of degree $k$ which satisfy

$$
\left\langle B_{i}^{k}, D_{j}^{k}\right\rangle^{[\alpha, \beta]}=\delta_{i j}=\left\{\begin{array}{l}
1 \text { if } i=j  \tag{8}\\
0 \text { otherwise }
\end{array}, \quad i, j=0 \ldots k .\right.
$$

The polynomials $D_{j}^{k}$ can be represented with respect to the Bernstein basis,

$$
\begin{equation*}
D_{i}^{k}(t)=\frac{1}{h} \sum_{j=0}^{k} c_{i, j} B_{j}^{k}(t), \quad i=0, \ldots, k, \tag{9}
\end{equation*}
$$

with the coefficients

$$
\begin{equation*}
c_{p, q}=\frac{(-1)^{p+q}}{\binom{k}{p}\binom{k}{q}} \sum_{j=0}^{\min (p, q)}(2 j+1)\binom{k+j+1}{k-p}\binom{k-j}{k-p}\binom{k+j+1}{k-q}\binom{k-j}{k-q} \tag{10}
\end{equation*}
$$

which have been derived by Jüttler (1998), and $h=\beta-\alpha$. Alternatively, these polynomials can be computed using a recurrence relation involving dual basis polynomials of lower degree and Legendre polynomials (Ciesielski, 1987).

The polynomial $q$ obtained by applying degree reduction to $p$ (see (2) and (7)) with respect to the interval $[\alpha, \beta]$ may be computed from

$$
\begin{equation*}
q(t)=\sum_{j=0}^{k}\left\langle p(t), D_{j}^{k}(t)\right\rangle^{[\alpha, \beta]} B_{j}^{k}(t)=\sum_{j=0}^{k}\left(\sum_{i=0}^{n} b_{i} \beta_{i, j}^{n, k}\right) B_{j}^{k}(t), \tag{11}
\end{equation*}
$$

with the coefficients

$$
\begin{equation*}
\beta_{i, j}^{n, k}=\left\langle B_{i}^{n}(t), D_{j}^{k}(t)\right\rangle^{[\alpha, \beta]} . \tag{12}
\end{equation*}
$$

Using the identity

$$
\begin{equation*}
\left\langle B_{i}^{m}, B_{j}^{n}\right\rangle^{[\alpha, \beta]}=h \frac{\binom{m}{i}\binom{n}{j}}{(m+n+1)\binom{m+n}{i+j}}, \tag{13}
\end{equation*}
$$

these coefficients can be computed from (9) and (10). Note that these coefficients do not depend on the interval $[\alpha, \beta]$, since the factors $h$ in (9) and (13) cancel each other.

Example 1 The degree reduction coefficients for $n=5$ and $k=2$ form the matrix

$$
\left(\beta_{i, j}^{5,2}\right)_{i=0, ., 5 ; j=0, \ldots, 2}=\left[\begin{array}{ccc}
\frac{23}{28} & -\frac{3}{7} & \frac{3}{28}  \tag{14}\\
\frac{9}{28} & \frac{2}{7} & -\frac{3}{28} \\
0 & \frac{9}{14} & -\frac{1}{7} \\
-\frac{1}{7} & \frac{9}{14} & 0 \\
-\frac{3}{28} & \frac{2}{7} & \frac{9}{28} \\
\frac{3}{28} & -\frac{3}{7} & \frac{23}{28}
\end{array}\right] .
$$

The coefficients of $q$ are obtained by multiplying the row vector $\left(b_{0}, \ldots, b_{5}\right)$ of the coefficients of $p$ by this matrix.

### 2.3 Bézier clipping and its convergence rate

Bézier clipping, see Algorithm 1 (bezclip), uses the convex hull property of Bernstein-Bézier representations in order to generate one or more intervals of maximum length $\varepsilon$ which contain(s) the roots.

The polynomial $p$ is represented by its Bézier coefficients with respect to the current interval $[\alpha, \beta]$. The graph of $p$ can be described as a parametric Bézier curve with control points

$$
\begin{equation*}
\mathbf{b}_{i}=\left(\frac{(n-i) \alpha+i \beta}{n}, b_{i}\right), \quad i=0, \ldots, n . \tag{15}
\end{equation*}
$$

Due to the convex-hull property, the graph lies within the convex hull $\mathcal{C}$ of the control points $\left(\mathbf{b}_{i}\right)_{i=0, \ldots, n}$. Consequently, all roots of the polynomial $p$ are

```
\(\begin{array}{ll}\text { Algorithm } 1 \text { bezclip }(p,[\alpha, \beta]) & \text { \{Bézier clipping\} }\end{array}\)
    if length of interval \([\alpha, \beta] \geq \varepsilon\) then
        \(\mathcal{C} \leftarrow\) convex hull of the control points of \(p\) with respect to \([\alpha, \beta]\).
        if \(\mathcal{C}\) intersects \(t\)-axis then
            Find \(\left[\alpha^{\prime}, \beta^{\prime}\right]\) by intersecting \(\mathcal{C}\) with the \(t\)-axis.
            if \(\left|\alpha^{\prime}-\beta^{\prime}\right|<\frac{1}{2}|\alpha-\beta|\) then
                    return (bezclip \(\left.\left(p,\left[\alpha^{\prime}, \beta^{\prime}\right]\right)\right)\)
            else
                    return \(\left(\operatorname{bezclip}\left(p,\left[\alpha, \frac{1}{2}(\alpha+\beta)\right]\right) \cup \operatorname{bezclip}\left(p,\left[\frac{1}{2}(\alpha+\beta), \beta\right]\right)\right)\).
            end if
        else
            return (Ø)
        end if
    else
        return \(([\alpha, \beta])\)
    end if
```

Fig. 1. Bézier clipping: The next interval containing the roots is obtained by intersecting the convex hull of the control polygon with the $t$-axis.
contained in the interval which is obtained by intersecting $\mathcal{C}$ with the $t$-axis. This observation, which is illustrated by Figure 1, is used in lines $2-4$ of the algorithm to generate the next interval.

In line 6, the de Casteljau algorithm is applied twice to generate the coefficients with respect to the subinterval $\left[\alpha^{\prime}, \beta^{\prime}\right]$. Similar, it is applied once in line 8 , in order to bisect the interval.

For any root contained in $[0,1]$, the call $\operatorname{bezclip}(p,[0,1])$ returns an interval
containing that root. Bézier clipping may produce false positive answers (i.e., intervals not containing any root) if the graph of the polynomial gets very close to the $t$-axis.

In order to study the efficiency of Bézier clipping, we analyze the sequence $\left(h_{i}\right)_{i=0}^{\infty}$ of the lengths of the intervals $[\alpha, \beta]$ generated after calling bezclip $i$ times. Note that algorithm bezclip acts recursively, and combines bisection with clipping steps. Here we follow only one path in the execution tree which leads towards one of the roots. As observed by Nishita and Sederberg (1990), this sequence has convergence rate 2 , provided that it leads to a single root. In the case of multiple roots, however, only linear convergence is achieved. (See Gautschi (1997) for more information about convergence rates).

## 3 Computing roots via degree reduction

We describe a new algorithm for isolating the roots and analyze its convergence rates in the cases of roots with multiplicities 1 and 2.

### 3.1 Algorithm

Based on degree reduction to a quadratic polynomial ( $k=2$ ), we propose a new technique for computing the roots, see Algorithm 2 (quadclip).

Some steps of the algorithm will be explained in more detail:

- In line 2 of the algorithm, we generate the best quadratic approximant $q$ with respect to the $L^{2}$ norm on the current interval $[\alpha, \beta]$, see Fig. 2 (left). This is achieved by multiplying the row vector of Bézier coefficients of $p$ with the degree reduction matrix $\left(\beta_{i, j}^{n, 2}\right)_{i=0, \ldots, n ; j=0,1,2}$. These coefficients are precomputed and stored in a lookup-table.
- In order to obtain the bound $\delta$ on

$$
\begin{equation*}
\|p-q\|_{\infty}^{[\alpha, \beta]}=\max _{t \in[\alpha, \beta]}|p(t)-q(t)|, \tag{16}
\end{equation*}
$$

see line 3, we raise the degree of the Bernstein-Bézier representation of the quadratic polynomial $q$ to $n$. Similar to degree reduction, this is achieved by multiplying the row vector of Bézier coefficients of $q$ with the degree raising matrix $\left(\beta_{i, j}^{2, n}\right)_{i=0,2,1 ; j=0, \ldots, n}$. These coefficients are again precomputed and stored in a lookup-table, see Example 2. The bound is chosen as

$$
\begin{equation*}
\delta=\max _{i=0, \ldots, n}\left|b_{i}-c_{i}\right|, \tag{17}
\end{equation*}
$$

```
Algorithm 2 quadclip \((p,[\alpha, \beta])\)
\{Quadratic clipping\}
    if length of interval \([\alpha, \beta] \geq \varepsilon\) then
        \(q \leftarrow\) generate a quadratic polynomial by applying degree reduction with re-
        spect to the \(L^{2}\) inner product on \([\alpha, \beta]\) to \(p\).
        \(\delta \leftarrow\) compute bound on \(\|p-q\|_{\infty}^{[\alpha, \beta]}\) by comparing the Bernstein-Bézier rep-
        resentations of \(p\) and \(q\).
        \(m \leftarrow q-\delta\) \{lower bound\}
        \(M \leftarrow q+\delta\) \{upper bound \(\}\)
        if the strip enclosed by \(m, M\) does not intersect the \(t\)-axis within \([\alpha, \beta]\) then
            return (Ø)
        else
            Find intervals \(\left[\alpha_{i}, \beta_{i}\right], i=1, \ldots, k\), by intersecting \(m, M\) with the \(t\)-axis.
            The number \(k\) of intervals is either 1 or 2 .
            if \(\max _{i=1, \ldots, k}\left|\alpha_{i}-\beta_{i}\right|>\frac{1}{2}|\alpha-\beta|\) then
            return (quadclip \(\left(p,\left[\alpha, \frac{1}{2}(\alpha+\beta)\right]\right) \cup\) quadclip \(\left.\left(p,\left[\frac{1}{2}(\alpha+\beta), \beta\right]\right)\right)\).
        else
            \(S \leftarrow \emptyset\)
            for \(i=1, \ldots, k\) do
                    \(S \leftarrow S \cup\) quadclip \(\left(p,\left[\alpha_{i}, \beta_{i}\right]\right)\)
            end for
            return ( \(S\) )
            end if
        end if
    else
        return \(([\alpha, \beta])\)
    end if
```

see Fig. 2 (left), where $b_{i}$ and $c_{i}$ are the coefficients of the Bernstein-Bézier representations of $p$ and $q$ of degree $n$ with respect to $[\alpha, \beta]$, respectively.

- In lines 4 and 5 , the bound $\delta$ is used to construct quadratic polynomials $m$ and $M$ satisfying

$$
\begin{equation*}
\forall t \in[\alpha, \beta]: \quad m(t) \leq p(t) \leq M(t) . \tag{18}
\end{equation*}
$$

- In lines 6-19 we analyze the strip enclosed by $m$ and $M$ and its intersection with the $t$-axis, see Fig. 2, right. If the intersection is empty, then no roots exist. Otherwise, the intersection consists of either one or two intervals that contain the roots. Their boundaries are found by solving two quadratic equations, see Remark 3.
- If the length(s) of this/these interval(s) is/are sufficiently small, when compared to the length of the previous interval $[\alpha, \beta]$, then quadclip is applied to them (lines 14-16). Otherwise we bisect the interval $[\alpha, \beta]$ and apply quadclip to the two halves (line 11).

For any root contained in $[0,1]$, the call quadclip $(p,[0,1])$ returns an interval containing that root. Similar to Bézier clipping, quadratic clipping may

Fig. 2. One iteration of quadclip in the case of a single root. Left: the polynomial $p$ and its quadratic approximation $q$, along with the control polygons. The error bound $\delta$ is obtained as the maximum length of the thick grey vertical bars. Right: the lower and upper bounds $m=q-\delta$ and $M=q+\delta$. The intersection of the strip enclosed by them with the $t$-axis defines the new interval $\left[\alpha^{\prime}, \beta^{\prime}\right]$.
produce false positive answers (i.e., intervals not containing any root) if the graph of the polynomial gets very close to the $t$-axis.

Example 2 The degree raising coefficients for $n=5$ and $k=2$ form the matrix

$$
\left(\beta_{i, j}^{2,5}\right)_{i=1, \ldots, 2 ; j=0, \ldots, 5}=\left[\begin{array}{cccccc}
1 & \frac{3}{5} & \frac{3}{10} & \frac{1}{10} & 0 & 0  \tag{19}\\
0 & \frac{2}{5} & \frac{3}{5} & \frac{3}{5} & \frac{2}{5} & 0 \\
0 & 0 & \frac{1}{10} & \frac{3}{10} & \frac{3}{5} & 1
\end{array}\right] .
$$

Remark 3 The roots of a quadratic polynomial (cf. lines 6 and 9 of the algorithm) $g(t)=B_{0}^{2}(t) d_{0}+B_{1}^{2}(t) d_{1}+B_{2}^{2}(t) d_{2}$ are $t_{1 \mid 2}=\left(1-\tau_{1 \mid 2}\right) \alpha+\tau_{1 \mid 2} \beta$ where

$$
\begin{equation*}
\tau_{1 \mid 2}=\frac{d_{1}-d_{0} \pm \sqrt{D}}{d_{2}-2 d_{1}+d_{0}} . \tag{20}
\end{equation*}
$$

with $D=d_{1}^{2}-d_{0} d_{2}$. If $\left|d_{2}-2 d_{1}+d_{0}\right|$ is below a user-defined threshold (which depends on the accuracy of the numerical computation), then the computation of the roots via (20) becomes numerically unstable. In this situation we apply Bézier clipping to the control polygon of $g$ in order to bound the roots.

### 3.2 Convergence rate

In order to make this paper self-contained, we start this section by formulating two technical lemmas.

Lemma 4 For any given polynomial $p$, there exists a constant $C_{p}$ depending solely on $p$, such that for all intervals $[\alpha, \beta] \subseteq[0,1]$ the bound $\delta$ generated in line 3 of Algorithm quadclip satisfies $\delta \leq C_{p} h^{3}$, where $h=\beta-\alpha$.

Proof. Due to the equivalence of norms in finite-dimensional real linear spaces, there exist constants $C_{1}$ and $C_{2}$ such that

$$
\begin{equation*}
\forall r \in \Pi^{n}: \quad\|r\|_{\mathrm{BB}, \infty}^{[\alpha, \beta]} \leq C_{1}\|r\|_{2}^{[\alpha, \beta]} \quad \text { and } \quad\|r\|_{2}^{[\alpha, \beta]} \leq C_{2}\|r\|_{\infty}^{[\alpha, \beta]} \tag{21}
\end{equation*}
$$

where the three norms are the maximum ( $\ell_{\infty}$ ) norm of the Bernstein-Bézier coefficients, the $L^{2}$ norm (4) and the maximum norm

$$
\begin{equation*}
\|r\|_{\infty}^{[\alpha, \beta]}=\max _{t \in[\alpha, \beta]}|r(t)|, \tag{22}
\end{equation*}
$$

all with respect to the interval $[\alpha, \beta]$. The constants $C_{1}$ and $C_{2}$ do not depend on the given interval $[\alpha, \beta]$, since all three norms are invariant with respect to affine transformations of the $t$-axis; cf. (5) and (6).

Consequently,

$$
\begin{align*}
& \delta=\|p-q\|_{\mathrm{BB}, \infty}^{[\alpha, \beta]} \leq C_{1}\|p-q\|_{2}^{[\alpha, \beta]} \leq C_{1}\left\|p-Q_{\alpha}\right\|_{2}^{[\alpha, \beta]} \leq \\
& \leq C_{1} C_{2}\left\|p-Q_{\alpha}\right\|_{\infty}^{[\alpha, \beta]} \leq \frac{1}{6} C_{1} C_{2} \max _{t_{0} \in[0,1]}\left|p^{\prime \prime \prime}\left(t_{0}\right)\right| h^{3}, \tag{23}
\end{align*}
$$

where $Q_{\alpha}$ is the quadratic Taylor polynomial at $t=\alpha$ to $p$ and $p^{\prime \prime \prime}$ is the third derivative.

Lemma 5 For any given polynomial $p$ there exist constants $V_{p}, D_{p}$ and $A_{p}$ depending solely on $p$, such that for all intervals $[\alpha, \beta] \subseteq[0,1]$ the quadratic polynomial $q$ obtained by applying degree reduction to $p$ satisfies

$$
\begin{equation*}
\|p-q\|_{\infty}^{[\alpha, \beta]} \leq V_{p} h^{3}, \quad\left\|p^{\prime}-q^{\prime}\right\|_{\infty}^{[\alpha, \beta]} \leq D_{p} h^{2}, \text { and }\left\|p^{\prime \prime}-q^{\prime \prime}\right\|_{\infty}^{[\alpha, \beta]} \leq A_{p} h, \tag{24}
\end{equation*}
$$

with $h=\beta-\alpha$, where $\|.\|_{\infty}^{[\alpha, \beta]}$ is defined as in (22).

Proof. Similar to the proof of the previous lemma, it can be shown that the norm

$$
\begin{equation*}
\|r\|_{\star}^{[\alpha, \beta]}=\|r\|_{\infty}^{[\alpha, \beta]}+h\left\|r^{\prime}\right\|_{\infty}^{[\alpha, \beta]}+h^{2}\left\|r^{\prime \prime}\right\|_{\infty}^{[\alpha, \beta]}, \tag{25}
\end{equation*}
$$

satisfies

$$
\begin{equation*}
\|r\|_{\star}^{[\alpha, \beta]} \leq C_{3}\|r\|_{2}^{[\alpha, \beta]} \tag{26}
\end{equation*}
$$

where the constant $C_{3}$ does not depend on the interval $[\alpha, \beta]$, again due to the affine invariance. Therefore, and using similar arguments as in the previous proof,

$$
\begin{gather*}
\|p-q\|_{\star}^{[\alpha, \beta]}=\|p-q\|_{\infty}^{[\alpha, \beta]}+h\left\|p^{\prime}-q^{\prime}\right\|_{\infty}^{[\alpha, \beta]}+h^{2}\left\|p^{\prime \prime}-q^{\prime \prime}\right\|_{\infty}^{[\alpha, \beta]} \leq \\
\leq C_{3}\|p-q\|_{2}^{[\alpha, \beta]} \leq C_{3}\left\|p-Q_{\alpha}\right\|_{2}^{[\alpha, \beta]} \leq C_{2} C_{3}\left\|p-Q_{\alpha}\right\|_{\infty}^{[\alpha, \beta]} \leq  \tag{27}\\
\leq \frac{1}{6} C_{2} C_{3} \max _{t_{0} \in[0,1]}\left|p^{\prime \prime \prime}\left(t_{0}\right)\right| h^{3},
\end{gather*}
$$

where $Q_{\alpha}$ is the quadratic Taylor polynomial at $t=\alpha$ to $p$. Clearly, this implies (24)

Now we are able to analyze the speed of convergence. The case of single and double roots will be dealt with separately. In the case of single roots, we obtain the following result.

Theorem 6 If the polynomial $p$ has a root $t^{\star}$ in $[\alpha, \beta]$ and provided that this root has multiplicity 1, then the sequence of the lengths of the intervals generated by quadclip which contain that root has the convergence rate $d=3$.

Proof. The call quadclip $(p,[0,1])$ generates a sequence of intervals

$$
\begin{equation*}
\left(\left[\alpha_{i}, \beta_{i}\right]\right)_{i=0,1,2, \ldots} \tag{28}
\end{equation*}
$$

with the lengths $h_{i}=\beta_{i}-\alpha_{i}$ whose boundaries converge to $t^{\star}$. We assume that the first derivative satisfies $p^{\prime}\left(t^{\star}\right)>0$. If this assumption is violated, one may consider the polynomial $-p$ instead of $p$.

Let $q_{i}$ be the quadratic polynomial obtained by degree reduction with respect to the interval $\left[\alpha_{i}, \beta_{i}\right]$. Since $p^{\prime}$ is continuous and due to Lemma 5 , the inequalities

$$
\begin{equation*}
\left\|p^{\prime}-p^{\prime}\left(t^{\star}\right)\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{4} p^{\prime}\left(t^{\star}\right) \quad \text { and } \quad\left\|q_{i}^{\prime}-p^{\prime}\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{4} p^{\prime}\left(t^{\star}\right) \tag{29}
\end{equation*}
$$

hold for all but finitely many values of $i$, where the maximum norm refers to the interval $\left[\alpha_{i}, \beta_{i}\right]$. These two inequalities imply

$$
\begin{equation*}
\left\|q_{i}^{\prime}-p^{\prime}\left(t^{\star}\right)\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{2} p^{\prime}\left(t^{\star}\right), \quad \text { hence } \quad \forall t \in\left[\alpha_{i}, \beta_{i}\right]: q_{i}^{\prime}(t)>\frac{1}{2} p^{\prime}\left(t^{\star}\right) . \tag{30}
\end{equation*}
$$

On the other hand, the vertical width $2 \delta_{i}$ of the strip enclosed by $m$ and $M$ is bounded by $2 C_{p} h_{i}^{3}$, due to Lemma 4 . Thus, the lengths $h_{i}$ of the intervals

Fig. 3. Proof of Eq. (31)

Fig. 4. One iteration of quadclip in the case of a double root. See caption of Figure 2.
satisfy

$$
\begin{equation*}
h_{i+1} \leq \frac{4 C_{p}}{p^{\prime}\left(t^{\star}\right)} h_{i}^{3} \tag{31}
\end{equation*}
$$

for all but finitely many values of $i$, see Fig. 3.

As for Bézier clipping, multiple roots slow down the speed of convergence. However, the rate is still super-linear for double roots, as described in the following Theorem. See Figure 4 for an illustration.

Theorem 7 If the polynomial $p$ has a root $t^{\star}$ in $[\alpha, \beta]$ and provided that this root has multiplicity 2 , then the sequence of the lengths of the intervals gener-
ated by quadclip which contain that root has the convergence rate $d=\frac{3}{2}$.

Proof. Similar to the proof of the previous Theorem, we analyze the sequence (28) of intervals with lengths $h_{i}$ generated by the algorithm which contain the double root. We assume that the second derivative satisfies $p^{\prime \prime}\left(t^{\star}\right)>0$. If this assumption is violated, one may again consider the polynomial $-p$ instead of $p$.

Again, let $q_{i}$ be the quadratic polynomial obtained by degree reduction with respect to the interval $\left[\alpha_{i}, \beta_{i}\right]$, and let $\delta_{i}$ be the associated distance bound obtained in line 3 of the algorithm. Since $p^{\prime \prime}$ is continuous and due to Lemma 5, the inequalities

$$
\begin{equation*}
\left\|p^{\prime \prime}-p^{\prime \prime}\left(t^{\star}\right)\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{4} p^{\prime \prime}\left(t^{\star}\right) \quad \text { and } \quad\left\|q_{i}^{\prime \prime}-p^{\prime \prime}\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{4} p^{\prime \prime}\left(t^{\star}\right) \tag{32}
\end{equation*}
$$

hold for all but finitely many values of $i$, where the maximum norm refers to the interval $\left[\alpha_{i}, \beta_{i}\right]$. These two inequalities imply

$$
\begin{equation*}
\left\|q_{i}^{\prime \prime}-p^{\prime \prime}\left(t^{\star}\right)\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq \frac{1}{2} p^{\prime \prime}\left(t^{\star}\right), \quad \text { hence } \quad \forall t \in\left[\alpha_{i}, \beta_{i}\right]: q_{i}^{\prime \prime}(t)>\frac{1}{2} p^{\prime \prime}\left(t^{\star}\right) . \tag{33}
\end{equation*}
$$

We consider the lower bound $m_{i}=q_{i}-\delta_{i}$ obtained by applying degree reduction with respect to the interval $\left[\alpha_{i}, \beta_{i}\right]$. Due to $p^{\prime \prime}\left(t^{\star}\right)>0$, its intersections with the $t$-axis bound the next interval $\left[\alpha_{i+1}, \beta_{i+1}\right]$ for all but finitely many values of $i$. Let

$$
\begin{equation*}
m_{i}=\frac{a_{i}}{2}\left(t-t^{\star}\right)^{2}+b_{i}\left(t-t^{\star}\right)+c_{i} \tag{34}
\end{equation*}
$$

with certain real coefficients $a_{i}=q_{i}^{\prime \prime}\left(t^{\star}\right), b_{i}=q_{i}^{\prime}\left(t^{\star}\right)$ and $c_{i}$. According to (33), the leading coefficient satisfies

$$
\begin{equation*}
a_{i} \geq \frac{1}{2} p^{\prime \prime}\left(t^{\star}\right) \tag{35}
\end{equation*}
$$

for all but finitely many values of $i$. Due to the two Lemmas and to $p^{\prime}\left(t^{\star}\right)=0$, the other two coefficients satisfy

$$
\begin{equation*}
\left|b_{i}\right|=\left|p^{\prime}\left(t^{\star}\right)-q^{\prime}\left(t^{\star}\right)\right| \leq\left\|p^{\prime}-q^{\prime}\right\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]} \leq D_{p} h_{i}^{2} \tag{36}
\end{equation*}
$$

and

$$
\begin{gather*}
\left|c_{i}\right|=\left|p\left(t^{\star}\right)-m\left(t^{\star}\right)\right| \leq\left|p\left(t^{\star}\right)-q\left(t^{\star}\right)\right|+\left|q\left(t^{\star}\right)-m\left(t^{\star}\right)\right| \\
\leq\|p-q\|_{\infty}^{\left[\alpha_{i}, \beta_{i}\right]}+\delta_{i} \leq\left(V_{p}+C_{p}\right) h_{i}^{3} . \tag{37}
\end{gather*}
$$

The coefficients $c_{i}$ are non-positive, $c_{i} \leq 0$.

Table 1
Convergence rates of the algorithms quadclip and bezclip.

| root multiplicity | single root | double root | triple root, etc. |
| :---: | :---: | :---: | :---: |
| quadclip | 3 | $\frac{3}{2}$ | 1 |
| bezclip | 2 | 1 | 1 |

For all but finitely many values of $i$, the lengths of the interval $\left[\alpha_{i+1}, \beta_{i+1}\right]$ are bounded by the difference of the roots of the lower bound $m_{i}$, which leads to

$$
\begin{equation*}
h_{i+1} \leq 2 \sqrt{\frac{b_{i}^{2}}{a_{i}^{2}}-\frac{2 c_{i}}{a_{i}}} \leq \frac{\left|b_{i}\right|}{a_{i}}+\sqrt{\frac{2\left|c_{i}\right|}{a_{i}}} \leq \frac{2 D_{p}}{p^{\prime \prime}\left(t^{\star}\right)} h_{i}^{2}+\sqrt{\frac{4\left(C_{p}+V_{p}\right)}{p^{\prime \prime}\left(t^{\star}\right)}} h_{i}^{3 / 2} \tag{38}
\end{equation*}
$$

Hence, the sequence $\left(h_{i}\right)_{i=0,1,2, \ldots}$ has the convergence rate $\frac{3}{2}$.

## 4 Comparison

We compare the two algorithms (Bézier clipping and quadratic clipping) with respect to five criteria: convergence rate, number of operations per iteration step, time per iteration step, number of iterations needed to achieve a certain prescribed accuracy, and computing time needed to achieve a certain prescribed accuracy.

### 4.1 Convergence rates, number of operations and time per iteration step

The results concerning the convergence rates are summarized in Table 1.
With respect to these rates, the new algorithm clearly performs better than Bézier clipping. However, the computational effort per iteration step is equally important. For instance, it is known that solving univariate equations by the secant method, where the convergence rate is $(1+\sqrt{5}) / 2 \approx 1.618$ for a single root, is generally faster than Newton's method with quadratic convergence rate, since it needs only one evaluation of the function per iteration step, while Newton's method needs one evaluation of the function and another one of the derivative. Consequently, the computational costs of two steps of the secant method and of one step of the Newton method are comparable.

Table 2 shows the number of operations needed per iteration step, where it is assumed that one new interval is found (i.e., $k=1$ in line 9 of Algorithm 2) and that this interval has shrunk by more than $\frac{1}{2}$, cf. line 5 of Algorithm 1 and line 10 of Algorithm 2. Also, the number of operations needed for computing

Table 2
Number of operations per step of the iteration for various values of the degree $n$.

| degree <br> $n$ | quadclip |  |  |  |  |  | bezclip |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\pm$ | $* \div$ | $\leq$ | $\sqrt{ }$ | $\|\cdot\|$ | $\sum$ | $\pm$ | $* \div$ | $\leq$ | $\sqrt{ }$ | $\|\cdot\|$ | $\sum$ |
| 2 | 120 | 75 | 30 | 4 | 0 | 229 | 90 | 30 | 5 | 0 | 0 | 125 |
| 4 | 228 | 115 | 32 | 4 | 2 | 385 | 214 | 62 | 9 | 0 | 0 | 285 |
| 8 | 548 | 243 | 30 | 4 | 2 | 827 | 582 | 174 | 17 | 0 | 0 | 773 |
| 16 | 1676 | 691 | 30 | 4 | 2 | 2403 | 1698 | 590 | 33 | 0 | 0 | 2321 |

Table 3
Time per iterations in microseconds for various degrees $n$.

| degree of the polynomial | 2 | 4 | 8 | 16 |
| :---: | :---: | :---: | :---: | :---: |
| quadclip | 2.0 | 2.8 | 4.4 | 9.6 |
| bezclip | 1.3 | 1.9 | 3.5 | 8.3 |

the convex hull for Algorithm 1 varies slightly; here we assume to have a convex control polygon, since this is the limit case in general.

The classical Bézier clipping has a slight advantage, though the computational costs of both methods are roughly comparable. The number of operations grows quadratically with the degree $n$. For both algorithms, the computational effort grows linearly, except for the quadratic grow caused by de Casteljau's algorithm which is used to generate the Bernstein-Bézier representation with respect to the newly generated interval. For large degrees $n$, the de Casteljau algorithm dominates the overall computational costs and the computational costs of both algorithms become increasingly similar.

This picture becomes even more clear by comparing the computation times. We implemented both algorithms in C on a PC with a Intel(R) Xeon(TM) CPU ( 2.40 GHz ) with 512 KB of RAM running Linux and measured the time needed for $10^{5}$ iterations (in order to obtain a measurable quantity). The results are reported in Table 3.

In addition, Fig. 5a shows the relation between computing times and polynomial degree, and Fig. 5b visualizes the ratio $t_{\text {quadclip }} / t_{\text {bezclip }}$. For large values of the degree $n$, the ratio tends to 1 , since the computational effort of the de Casteljau algorithm becomes increasingly dominant.

### 4.2 Number of iterations and computing times vs. accuracy

In order to analyze the relation between the computational effort and the desired accuracy, we discuss three examples, which represent polynomials with a single root, a double root, and two roots which are very close ("near double

Fig. 5. a) Time per $10^{5}$ iterations of algorithms quadclip and bezclip. b) Ratio of computing times of both algorithms.
root").
Example 8 (Single root) We applied the algorithms bezclip and quadclip to the four polynomials

$$
\begin{aligned}
& f_{2}(t)=\left(t-\frac{1}{2}\right)(3-t), \quad f_{4}(t)=\left(t-\frac{1}{3}\right)(2-t)(t+5)^{2}, \\
& f_{8}(t)=\left(t-\frac{1}{3}\right)(2-t)^{3}(t+5)^{4}, \quad f_{16}(t)=\left(t-\frac{1}{3}\right)(2-t)^{5}(t+5)^{10}
\end{aligned}
$$

in order to compute the single root $\frac{1}{3}$ in the interval $[0,1]$. Table 4 reports the number of iterations and the computing times for various values of the desired accuracy $\varepsilon$. The numbers of iterations were obtained from an implementation in Maple, while the computing times were measured with the help of the implementation in C. The computing times for accuracy below $10^{-16}$ were obtained by multiplying the number of iterations with the time per iteration (see Table 3). In addition, Figure 6 visualizes the relation between computing times and desired accuracy.

For these four polynomials, the new algorithm (quadclip) performs slightly better than Bézier clipping, though the difference is not that significant: the overall computing times to achieve a certain accuracy are roughly the same. In particular, this is true for the realistic range of accuracy (no more than 16 significant digits). This is due to the fact that the quadratic convergence rate of Bézier clipping is already very fast.

Example 9 (Double root) We applied the algorithms bezclip and quadclip to the four polynomials

$$
\begin{aligned}
& f_{2}(t)=\left(t-\frac{1}{2}\right)^{2}, \quad f_{4}(t)=\left(t-\frac{1}{2}\right)^{2}(t+2)(3-t), \\
& f_{8}(t)=\left(t-\frac{1}{2}\right)^{2}(4-t)^{3}(t+5)^{2}(t+7) \\
& f_{16}(t)=\left(t-\frac{1}{2}\right)^{2}(4-t)^{7}(t+5)^{6}(t+7)
\end{aligned}
$$

Table 4
Example 8 (single root): Number of iterations $N$ and computing time $t$ in $\mu s$ for various values of degree $n$ and accuracy $\varepsilon$. The times for more than 16 significant digits (shown in italic) have been obtained by extrapolation.

Fig. 7. Example 9 (double root): Computing time $t$ in $10^{-5} s$ vs. accuracy. The times for more than 16 significant digits have been obtained by extrapolation.
in order to compute the double root $\frac{1}{2}$ in the interval $[0,1]$. Table 5 reports the number of iterations and the computing times for various values of the desired accuracy $\varepsilon$. Again, the numbers of iterations were obtained from an implementation in Maple, while the computing times were measured with the help of the implementation in C. The computing times for accuracy below $10^{-16}$ were obtained by multiplying the number of iterations with the time per iteration (see Table 3). In addition, Figure 7 visualizes the relation between computing times and desired accuracy.

For these four polynomials, the new algorithm (quadclip) performs far better than Bézier clipping. This is due to the higher convergence rate (1.5) of the new algorithm.

Table 6

\end{aligned}
$$

in order to compute the two roots which are contained within the interval $[0,1]$. Table 6 reports the number of iterations and the computing times for various values of the desired accuracy $\varepsilon$. Once again, the numbers of iterations were obtained from an implementation in Maple, while the computing times were measured with the help of the implementation in C. The computing times for accuracy below $10^{-16}$ were obtained by multiplying the number of iterations with the time per iteration (see Table 3). In addition, Figure 7 visualizes the relation between computing times and desired accuracy.

For these four polynomials, the new algorithm (quadclip) performs better than Bézier clipping, since bezclip achieves quadratic convergence only after the roots have been separated. Similar effects can be observed if the graph of the polynomial gets very close to the $t$ axis without intersecting it (two or more close conjugate-complex roots).

Fig. 8. Example 10 (near double root): Computing time $t$ in $10^{-5} s$ vs. accuracy. The times for more than 16 significant digits have been obtained by extrapolation.

## 5 Concluding remarks

Based on the techniques of degree reduction, we derived an algorithm for computing all roots of a given polynomial within a given interval, with a certain accuracy. We analyzed the convergence rates of the new technique and compared it with the classical technique of Bézier clipping. In the case of single roots, the new algorithm performs similarly to Bézier clipping. For double and near double roots, however, it reduces the computational effort. This is due to its superlinear convergence rate $\left(\frac{3}{2}\right)$ in the case of double roots.

As a direct generalization of the method, one may replace the quadratic polynomial $q$ by a cubic or even a quartic one. In this case, the formulas of Cardano and Ferrari are needed to compute the intersections of the bounding polynomial strip with the $t$-axis. Clearly, these computations are more involved than in the case of a quadratic polynomial. It is to be expected that such a generalized algorithm would provide an even higher convergence rate for single and double roots, and superlinear convergence for roots with multiplicities 3 and 4.

Our future work will focus on the extension of the technique to the multivariate case. In a first step, we will formulate an algorithm which is based on approximation by linear polynomials. We expect that this leads to an algorithm with quadratic convergence for single roots, leading to results comparable to those of Mourrain and Pavone (2005). In a second step, we are working on several ideas which are expected to lead to faster convergence for single roots and superlinear convergence for double roots.
